MATERIAL FOR TREATMENT OF A HEART VALVE, IN PARTICULAR A MITRAL VALVE

The present invention relates to a material for treating a heart valve, in particular a mitral valve of a heart. This treatment may consist of performing an annuloplasty, i.e. decreasing distention of the annulus, or of strengthening the annulus of a normal valve. The invention also relates to a percutaneous method for performing a treatment of this type.

The annulus of a heart valve may, over time, be subject to distention leading to poor coaptation of the leaflets, resulting in decreased sealing of the valve.

To treat this ailment, it is well-known to perform an annuloplasty, i.e. a recalibration of the annulus using a member implanted on the valve annulus.

This annuloplasty member may be a prosthetic annulus fixed on the native valve annulus. This technique, however, has the drawback of involving open-heart surgery.

The annuloplasty member may also be a deformable member, able to be introduced using a catheter through minimally-invasive vascular access, then able to be delivered through the catheter and fixed near the valve annulus before being circumferentially withdrawn.

The existing annuloplasty members of this type, and the corresponding implantation techniques, like systems using the coronary sinuses, are not, however, fully satisfactory.

Moreover, it may be necessary to implant a prosthetic heart valve, in particular percutaneously using a catheter. Currently, this type of percutaneous implantation is difficult on the mitral valve of a heart, due essentially to the fact that the annulus of a mitral valve is elastic and may be distended during percutaneous implantation of a prosthetic valve.

The present invention essentially aims to resolve the drawbacks and gaps of the earlier techniques.

The concerned material comprises, in a known manner, an annuloplasty member able to be introduced using a catheter through minimally invasive vascular access, then to be delivered by said catheter and fixed to the valve annulus.

According to the invention, the material includes at least one catheter, comprising:

- at least one guide member able to be deployed from said catheter such that it extends along one portion of the valve annulus of the valve, in the immediate proximity of said valve annulus, and

- an implant having a helical shape engaged on said guide member, connected, with separation possibility, to actuation means making it possible to cause this implant to move forward while driving it in rotation around its axis; the implant can thus be deployed from the catheter while being simultaneously moved forward and driven in rotation along its axis, said rotation enabling the implant to penetrate the tissue of the valve annulus while being guided along said annulus by said guide member.

The material according to the invention thus allows the implant to be placed very precisely along a segment of the valve annulus, using minimally-invasive access. The guide member is retracted into the catheter after placement of the implant, only the latter part remaining in place at the valve annulus.

The implant may vary in length and can adopt an extended shape for introduction and a shortened shape for implantation, the passage of the implant to this shortened implantation shape making it possible to gather the valve annulus portion in which said implant is placed.

In this case, the implant allows performance of an annuloplasty.

2

For passage of the implant from its extended shape to its shortened shape, said implant is preferably made of a shape memory material. This implant may in particular be in a nickel and titanium alloy known by the name "nitinol".

The implant can also have an invariable or slightly variable length. The implant can then be used to prevent distention of the valve annulus portion in which it is implanted, and/or to form a stiff annular or semi-annular frame, making it possible to implant and anchor a prosthetic valve percutaneously, in particular a prosthetic valve placed on a deployable stent. The implant can also be used to perform an annuloplasty, said actuation means then comprising an abutment integral with the implant and an abutment integral with the catheter; once the implant has been deployed, the abutment integral with the implant meets the abutment integral with the catheter and thus limits the longitudinal progress of the implant without limiting the rotation of said implant; continuing rotation of the implant around its axis after this longitudinal progress limitation causes gathering of the annulus portion in which the implant is placed.

The implant can comprise coils having a uniform pitch. It can also comprise coils having a varied pitch, said pitch being greater at the distal part of the implant and smaller at the proximal part of the implant. During screwing of an implant of this type in the valve annulus, the proximal coils having the smaller pitch contract the portion of the annulus wherein the distal coils having the greater pitch were previously engaged, thereby causing this portion of the annulus to contract and thus performing an annuloplasty.

The aforementioned means for actuating the implant comprises a rod rotationally connected to the implant, this connection being releasable to allow, after placement of the implant, separation of said implant from said rod. This releasable connection may in particular consist of a releasable snap-locking arrangement of the rod and the implant, said arrangement being released through axial tension exerted on the rod so as to separate it from the corresponding end of the implant; this can also be done by unscrewing, or other similar releasable connection means.

Preferably, each guide member is connected to means for its actuation making it possible to rotate the guide member in relation to the catheter.

This rotation makes it possible to ensure that each guide member is indeed engaged along the edge of the valve annulus connected to the wall comprising said annulus.

Preferably, the catheter contains two deployable guide members as previously mentioned, a first of which can be engaged on one side of the valve and the second of which can be engaged on the other side of the valve, and the implant is engaged around these two guide members.

In this way, the implant is guided during its placement by these two guide members, on the two surfaces of the valve annulus.

Preferably, in this case, the guide member, which is found, once deployed, on the other surface of the valve relative to the catheter, may comprise a bearing portion able to bear against the surface of the valve opposite the catheter, making it possible to pinch this tissue between it and the end of the catheter.

This pinching makes it possible to ensure stable positioning of the catheter during deployment of the implant.

This bearing portion may be formed in particular by a distal portion of the guide member, designed to be deployed, which is connected by a bent portion to a proximal portion of the guide member intended to remain in the catheter, said bent portion allowing, after deployment, orientation of said distal portion substantially in the plane of the valve annulus.

3

This bent portion may in particular be generated by shape memory, then able to be made of "nitinol".

The implant can be placed from the commissure formed by two leaflets adjacent to the treated valve; in this case, when a guide member contained by the catheter must be deployed on the surface of the valve opposite the catheter, this deployment can be done by going through this commissure.

The implant can also be placed outside a commissure of this type, in which case the catheter, or another catheter comprised by the material, includes a piercing needle for the valve annulus. In particular, in this case, the material comprises:

- a first catheter containing said piercing needle, which is hollow;
- a guidance wire able to be slid through the needle;
- a second catheter, containing the aforementioned guide member(s) and implant, the guide member intended to extend on the surface of the valve opposite the second catheter being tubular and engaged on the guidance wire.

The first catheter makes it possible to perform the piercing and deploy the guidance wire; said guidance wire is left in place and said first catheter and the needle are removed; the second catheter is then introduced while being guided by the guidance wire; said guidance wire makes it possible to guide the guide member during its deployment.

When the material comprises two guide members each intended to be engaged on one of the surfaces of the valve or the valve annulus, as described above, the guide member intended to be engaged on the surface of the valve opposite the catheter advantageously being tubular and being engaged on this guidance wire.

Positioning of the catheter and engagement of the guide member on the surface of the valve opposite the catheter are thus done under optimal conditions.

According to one particular embodiment of the invention, the material comprises a guide member positioned such that it can be deployed on one side of the catheter diametrically opposite that on which another guide member is deployed.

These diametrically opposed guide members make it possible to ensure perfect positioning of the catheter as close as possible to the valve annulus, without rotating the guide members relative to the catheter, these two diametrically opposed guide members allowing self-shifting of the materials along the wall to which the annulus is connected.

The percutaneous operating method according to the invention comprises steps consisting of:

using at least one catheter, comprising:

- at least one guide member able to be deployed from said catheter so as to extend along a portion of the valve annulus of the valve, in the immediate vicinity of said valve annulus, and
- an implant having a helical shape engaged on said guide member, connected, with the possibility of being separated, to actuation means making it possible to move said implant forward while driving it in rotation along its axis;

deploying the implant from the catheter by causing said implant to move forward and driving it in rotation along its axis, said rotation allowing the implant to penetrate the tissue of the valve annulus while being guided along said annulus by said guide member.

The implant used may be longitudinally compressible and can adopt an extended introduction form and a shortened form making it possible to reduce the length of the annulus portion in which it is implanted.

The implant used can also have an invariable or slightly variable length, longitudinally.

4

In this case, the method may comprise a step consisting, after placement of the implant, of percutaneously implanting and anchoring a prosthetic valve.

The implant used may also comprise coils having an inconstant pitch, said pitch being larger at the distal part of the implant and smaller at the proximal part of said implant.

The method according to the invention may also comprise steps consisting of:

- deploying a first guide member and a second guide member, on the surface of the valve facing the catheter and on the surface of the valve opposite the catheter, respectively;
- positioning the two guide members in relation to each other so as to hold the valve tissue between the guide members.

The method according to the invention may also comprise steps consisting of:

- introducing the catheter at the commissure formed by two leaflets adjacent to the valve, and
- deploying a deployable member through said commissure.

The method according to the invention may also comprise steps consisting of:

- introducing, outside the commissures formed by the leaflets of the valve, a catheter including a piercing needle for the valve annulus;
- piercing the valve annulus using said needle;
- removing the needle and deploying, through the hole made by said needle, a guide member designed to be placed on the side of the valve opposite the catheter.

In this case, the method may in particular comprise steps consisting of:

- piercing said hole using a first catheter containing said needle;
- introducing, after piercing said hole, a guidance wire through this hole;
- leaving this guidance wire in place and removing said first catheter as well as the needle;
- introducing a second catheter, containing the aforementioned guidance wire(s) and implant, one of the guide members being tubular and engaged on the guidance wire.

The invention will be well-understood, and other characteristics and advantages thereof will appear, in reference to the appended diagrammatic drawing, illustrating, as non-limiting examples, several possible embodiments of the material it concerns.

FIG. 1 is a partial cross-section of a heart, in which a first catheter is introduced up to the mitral valve;

FIG. 2 is a cross-section of this valve, after piercing of a hole through the valve annulus, and of the first catheter;

FIGS. 3 to 8 are diagrammatic views of the material according to a first embodiment, and of a portion of the mitral valve, during the various successive steps in placing an implant to treat this valve;

FIGS. 9 to 12 are very simplified diagrammatic views of four steps in placing the implant according to a second embodiment;

FIGS. 13 and 14 are principle views of two steps in placing an implant according to another embodiment, and

FIGS. 15 and 16 are very simplified diagrammatic views, perspective and top views, respectively, of the material according to yet another embodiment.

For simplification, the parts or elements of one embodiment which are found identically or similarly in another embodiment will be identified using the same numeric references and will not be described again.

5

FIGS. 1 to 8 illustrate a material for treating a heart valve, in particular a mitral valve 101 of a heart 100 (cf. FIG. 1), which comprises a first catheter 1, diagrammatically illustrated in FIG. 2, and a second catheter diagrammatically illustrated in any of FIGS. 3 to 12.

As shown in FIG. 1, the first catheter 1 is introduced through the aorta 102, then bears against the heart wall at the ventricle 103 and is directed such that its free end is positioned at the valve 101, immediately below the annulus 104 thereof, as shown by FIG. 2.

Said catheter 1 contains a hollow needle 5 which, once the catheter has been positioned, is slid into the catheter 1 until it goes through the annulus 104. A guidance wire 6 is then slid inside the needle 5 until it goes past the auricular side of the valve 101.

The catheter 1 is then removed from the heart 100, without removing the wire 6, then the catheter 2 is introduced along said wire 6 until it in turn arrives against the valve 101 of the ventricular side (cf. FIGS. 3 and 4).

As shown by these FIGS. 3 and 4, said catheter 2 contains two deployable guide members 10, 11, an implant 12 having a helical shape and an actuating rod 13 connected to one end of the implant 12 with a rotating connection (for clarity of the drawing, the body of the catheter 2 is shown as being transparent).

The guide member 10 is tubular and is engaged on the wire 6, thus making it possible to guide the catheter 2 to the aforementioned position. It appears in FIG. 4 that this guide member 10 is designed to be engaged on the auricular side of the valve 101, through the hole 105 previously made by the needle 5.

The other guide member 11 is not tubular and is engaged in a lateral zone of the catheter 2, leading to the outside through a lateral opening 15 separate from the main end opening 16 of said catheter 2. Said guide member 11 is designed to be engaged on the ventricular side of the valve 101, through said lateral opening 15.

The distal part 10a of the guide member 10 intended to be deployed from the auricular side of the valve 101 is in a shape memory material. As shown in FIG. 5, once deployed, it assumes a bent shape, by shape memory.

It is shown in this FIG. 5 that the guide members 10 and 11 can be rotated relative to the catheter 2, along the axis of said catheter 2, such that, by this rotational movement, their parts 10a, 11a deployed outside the catheter 2 can be engaged at the bottom of the above-annular and sub-annular groove formed by the annulus 104 of the valve 101. FIG. 5 also shows that the guide member 10 can, once its distal portion 10a has adopted said bent shape, be slid into the catheter 2 in the proximal direction while the guide member 11 is either kept in position or slid in this same catheter 2 in the distal direction. The result, as shown in FIG. 6, is pinching of the valve tissue 101, along the annulus 104, which ensures that the catheter 2 is held perfectly in position.

As shown in FIGS. 3 to 8, the implant 12 is engaged both around the guide member 10 and around the guide member 11. Once the aforementioned immobilization of the catheter 2 has taken place, the implant 12 is moved forward using the rod 13 and is simultaneously driven in rotation in the direction of screwing of its coils. The distal end of this implant 12 is self-tapping, such that the implant 12 penetrates the tissue forming the annulus 104 (cf. FIG. 6).

FIG. 7 shows that the implant 12 is thus "screwed" into the tissue of the annulus 104 until an abutment 20 located at the proximal end of the implant 12 meets the tissue of the annulus 104.

6

The rod 13 is connected to this abutment 20 with separation possibility, for example by a releasable snap-locking arrangement and, once the implant 12 has been completely placed (cf. FIG. 8), suitable tension is exerted on the rod 13 so as to separate it from the abutment 20.

In the embodiment shown in FIGS. 3 to 8, the implant 12 is in a shape memory material and is such that before heating by the patient's organism, it adopts a longitudinally extended shape and once heated by the organism, it contracts longitudinally, the pitch of its coils decreasing, as appears in FIG. 8. This reduction in pitch makes it possible to contract the tissue of the annulus 104, which performs, in whole or in part, an annuloplasty, i.e. a reduction of a distention of the annulus 104.

After placement of the implant 12, the guide members 10 and 11 are removed by sliding, then the catheter 2 is removed, as is the guidance wire 6.

FIGS. 9 to 12 show, very diagrammatically, another embodiment of the material according to the invention, in which the implant 12 has a substantially invariable length. For clarity of the drawing, the guide members 10 and 11 were not illustrated.

In this case, the catheter 2 and the actuating rod 13 comprise respective abutment surfaces 22 and 23, which meet at the end of introduction of the implant 12 in the annulus 104, this meeting blocking the forward motion of the implant 12, but not preventing said implant 12 from being driven in rotation along its axis.

From the position shown in FIG. 9, the implant 12 is introduced into the annulus 104, until the abutment 23 arrives against the abutment 22 (cf. FIG. 10); the abutment 20 is, in this embodiment, equipped with anchors 20a able to penetrate the tissue of the annulus 104 and, in this same position, these anchors 20a are found near the wall of the annulus 104, but without penetrating said wall.

Rotation of the implant 12 along its axis is then continued, which, in light of the longitudinal immobilization of said implant 12, causes movement, in the proximal direction of the catheter 2, of portions of the annulus 104 gone through by the respective coils of the implant 12. This movement makes it possible to compress the tissue forming said annulus 104 and, simultaneously, to cause the anchors 20a to penetrate the wall of this tissue, ensuring the immobilization of the implant 12 in rotation (cf. FIG. 11).

The abutment 20 can then be separated from the rod 13, as previously described (cf. FIG. 12).

FIGS. 13 and 14 show a third embodiment of the material according to the invention, in which the implant 12 comprises coils having an inconsistent pitch, this pitch being larger at the coils 12a located in the distal part of the implant 12 and smaller at the coils 12b located in the proximal part of this implant.

As can be understood from comparing FIGS. 13 and 14, during screwing of the implant 12 into the annulus 104, the proximal coils 12b having the smaller pitch contract the portion of the annulus 104 wherein the distal coils having the larger pitch were previously engaged, thereby causing this portion of the annulus 104 to contract and thus performing an annuloplasty.

FIGS. 15 and 16 show a variation of an embodiment of the material, in which the catheter 2 comprises, in addition to the guide members 10 and 11, a third guide member 25, diametrically opposite the guide member 11. This guide member 25 can be deployed through an opening 26 of said catheter 2 diametrically opposite the opening 15.

7

These two guide members **11, 25** make it possible to ensure perfect positioning of the catheter **2** as close as possible to the annulus **104**, as shown in FIG. **16**.

As appears from the preceding, the invention provides a material for treating a heart valve, in particular a mitral valve of a heart, that is fully satisfactory and makes it possible to conduct either annuloplasties or reinforcements of the valve annulus under optimal conditions.

It goes without saying that the invention is not limited to the embodiment described above as an example, but that it extends to all forms of embodiments covered by the appended claims.

The invention claimed is:

1. Material for treating a heart valve comprising:

a first guide member deployable from a distal end of a catheter, the guide member having a distal portion of a length that is configured to extend from the distal end of the catheter such that when the guide member is deployed for treating the heart valve the distal portion of the guide member extends from a proximal side to a distal side of a valve annulus to engage the distal side of the valve annulus;

a second deployable guide member slidably movable relative to the first guide member, the second guide member having a distal portion of a length that is configured to extend from the distal end of the catheter such that when the second guide member is deployed for treating the heart valve the distal portion of the second guide member extends from the distal end of the catheter to engage a proximal side of the valve annulus; and

an implant having a helical shape engaged around the first and second guide members and rotatable relative thereto, the implant being detachably connected to an actuator that is configured to cause the implant to advance distally along the first and second guide members while being rotated around the first and second guide members,

wherein the implant is configured to be deployed from the distal end of the catheter and to penetrate the tissue of the

8

valve annulus while advancing along and rotating relative to the deployed distal portions of the first and second guide members, and

wherein the implant remains engaged with and rotates around both of the deployed distal portions of the first and second guide members during advancement of the implant from the distal end of the catheter.

2. Material according to claim **1**, wherein the implant comprises coils having a varied pitch, said pitch being greater at a distal part of the implant and smaller at a proximal part of the implant.

3. Material according to claim **1**, further comprising: a piercing needle to penetrate a surface of the valve annulus.

4. Material for treating a heart valve, comprising:

a first catheter containing a hollow piercing needle;
a guidance wire configured to pass through the hollow piercing needle;

a guide member deployable from a second catheter, the guide member configured to extend on a surface of the valve annulus opposite the second catheter, wherein the guide member is tubular and is configured to extend along the guidance wire; and

an implant having a helical shape engaged around the guide member, and being detachably connected to an actuator configured to cause the implant to advance distally and rotate around its axis, the implant configured to be deployed from the second catheter and penetrate the tissue of the valve annulus while being guided along the valve annulus by the guide member.

5. Material according to claim **4**, further comprising:

a second guide member configured to engage a proximal surface of the valve annulus.

6. Material according to claim **5**, further comprising:

a third guide member positioned such that it can be deployed on one side of the second catheter diametrically opposite that on which the guide member is deployed.
